

FIN 513: Homework #3

Due on Tuesday, February 13, 2018

Wanbae Park

Problem 1

The put-call parity of American options on a currency is $e^{-r_f(T-t)}S - K \leq C - P \leq S - e^{-r_d(T-t)}K$ or $B^f S - K \leq C - P \leq S - B^d K$, where S and K denotes spot exchange rate and strike price as usual, r_d and r_f denotes domestic risk-free rate and foreign risk-free rate, respectively.

(Proof) Suppose not.

1. Suppose $C - P > S - e^{-r_d(T-t)}K$. Then an arbitrage opportunity exists by constructing the following portfolio.

- (a) Buy a put option and a unit of foreign currency.
- (b) Write a call option and borrow $e^{-r_d(T-t)}K$ amount of domestic currency on risk-free rate.

All possible situations can be separated by two cases: early exercise of written option occurs and no early exercise of written option. Assuming that early exercise occurs at $t^* < T$, payoff of the portfolio is as follows.

Case 1. Early exercise at $t^* < T$ occurs.

- (a) $e^{r_f(t^*-t)}S_{t^*}$
- (b) $-(S_{t^*} - K) - e^{-r_d(T-t^*)}K$

The sum of payoff from two strategies is $(e^{r_f(t^*-t)} - 1)S_{t^*} + (1 - e^{-r_d(T-t^*)})K$, which is positive.

Case 2. No early exercise.

- i. $S_T > K$
 - (a) $0 + e^{r_f(T-t)}S_T$
 - (b) $-(S_T - K) - K$
- ii. $S_T \leq K$
 - (a) $(K - S_T) + e^{r_f(T-t)}S_T$
 - (b) $0 - K$

In this case, the portfolio also has a positive payoff regardless of spot exchange rate at maturity.

Since the portfolio has a positive payoff at all possible situations, there must be a cost for implementing the strategies if there is no arbitrage opportunity. However, by the assumption, the initial cost for constructing portfolio is negative, so a contradiction occurs. Therefore, $C - P \leq S - e^{-r_d(T-t)}K$ must hold.

2. Suppose $C - P < e^{-r_f(T-t)}S - K$. Then there is also an arbitrage opportunity exists considering the following portfolio.

- (a) Buy a call option and invest K amount of domestic currencies on domestic risk-free rate.
- (b) Write a put option and sell short a foreign risk-free zero coupon bond.

By using similar procedure above, existence of arbitrage can be derived.

Case 1. Early exercise at $t^* < T$ occurs.

- (a) $e^{rt^*} K$
- (b) $-(K - S_{t^*}) - e^{-r_f(T-t^*)} S_{t^*}$

In this case, the sum of payoff from two strategies above is $S_{t^*}(1 - e^{-r_f(T-t^*)}) + (e^{rt^*} - 1)K$, which is positive.

Case 2. No early exercise.

- i. $S_T > K$
 - (a) $(S_T - K) + e^{r(T-t)} K$
 - (b) $0 - S_T$
- ii. $S_T \leq K$
 - (a) $0 + e^{r(T-t)} K$
 - (b) $-(K - S_T) - S_T$

At the maturity, the portfolio has a positive value regardless of spot exchange rate at T .

Since the portfolio has a positive payoff at all possible situations, there is an arbitrage opportunity since we assumed that there is a negative initial cost for constructing this portfolio. Therefore, $C - P \geq e^{-r_f(T-t)} S - K$ must hold.

Combining all results above, the put-call parity mentioned above must hold. Otherwise, there would be an arbitrage opportunity.

Problem 2

- (a) **False.** Even if $c(K, T) > S_t$, in order to lock arbitrage profit in, it needs to trade underlying asset. However, in this case, underlying asset is not tradable, constructing arbitrage portfolio is impossible.
- (b) **True.** Suppose $p(K, T) > B_{t,T} \cdot K$. Then by selling short a put option with strike price K and maturity T , and buying a zero coupon bond with face value K and maturity T . Note that there is a negative initial cost. If a spot price is larger than strike price at maturity, the payoff of portfolio would be equal to $K > 0$. Otherwise, the payoff would be equal to $-(K - S_T) + K = S_T$, which is also positive. Therefore, even if underlying asset is not tradable, by making a transaction of options and bonds, it is possible to make arbitrage profit.

- (c) **False.** Suppose $c(K, T_1) > c(K, T_2)$. Based on the principle of ‘buy low, sell high’, construct a portfolio by selling short $c(K, T_1)$ and buying $c(K, T_2)$. If spot price at T_1 is less than K , net profit would be positive since the written option would not be exercised. In contrast, if spot price at T_1 is greater than K , a negative payoff $K - S_T$ would be generated, and to make an arbitrage profit, it needs to deal with this payoff. Since the portfolio consists of a call option maturing at T_2 , selling short an underlying asset and investing K amount of dollars on risk free rate would make an arbitrage profit. However, since the underlying asset is non-tradable, implementing this strategy is impossible. It means that even if $c(K, T_1) > c(K, T_2)$, locking in an arbitrage profit is impossible.
- (d) **False.** The put-call parity assumes that tradable underlying asset. Since it is impossible to trade the underlying asset, put call parity does not hold.
- (e) **True.** Regardless of spot value, it is possible to make positive payoff by selling short two $c(K_1, T)$, and buying a $c(K_0, T)$ and $c(K_2, T)$. Since the strategy does not contain any underlying asset, if $c(K_0, T) - 2c(K_1, T) + c(K_2, T) \leq 0$, it is possible to make an arbitrage profit without trading underlying asset. Therefore, $c(K_0, T) - 2c(K_1, T) + c(K_2, T)$ should be positive.
- (f) **False.** If $c(K_2, T) \geq c(K_1, T)$, then arbitrage is possible. Construct a portfolio by selling short a $c(K_2, T)$ and buying a $c(K_1, T)$. Then it is possible to make an arbitrage profit. Table 1 shows details about arbitrage profit.

	$S_T < K_1$	$K_1 \leq S_T < K_2$	$K_2 \leq S_T$
<i>Long call</i>	0	$S_T - K_1$	$S_T - K_1$
<i>Short call</i>	0	0	$-(S_T - K_2)$
<i>Sum</i>	0	$S_T - K_1$	$K_2 - K_1$

Table 1: Payoff of portfolio

- (g) **False.** Proving $p(K, T) \geq \max(B_{t,T} \cdot K - S_t, 0)$ is equivalent to proving $p(K, T) \geq B_{t,T} \cdot K - S_t$, since option price is always greater than zero. Nevertheless, even though $p(K, T) \leq B_{t,T} \cdot K - S_t$, it is impossible to make an arbitrage profit. Since the formula contains S_t , it is inevitable to transact underlying asset to make an arbitrage profit. Therefore, since the underlying asset is non-tradable, making an arbitrage profit is impossible in this case.
- (h) **True.** Suppose $C(K, T) < c(K, T)$. Then by selling short European option and buying equal amount of American option, it is possible to make an arbitrage profit. It is because it is always possible to net European payoff out by exercising American option at maturity. Therefore, $C(K, T) \geq c(K, T)$ must hold.

Problem 3

- (a) Figure 1 represents plots of function f , g , h over the range -1 to 2.

Figure 1: $f(x)$, $g(x)$, $h(x)$ (from left to right)

- (b) From the figure 1, it seems that from $x = 0.5$ (approximately) the function f is convex since its slope starts increase at this point. Actually, using some calculus, since $h(x) = -\frac{2(x^3-9x^2-3x+3)}{(x^2+1)^3}$, $f(x)$ is convex from $x = 0.4422$.
- (c) It appears that from $x = -0.1$ to 0.8 (approximately) the function looks convex. It is because function $h(x)$ starts to increase at -0.1 and stops increasing at 0.8 .
- (d) Visually, it seems that from $x = -0.5$ to 0.4 $h(x)$ looks convex.

Problem 4

- (a) There is an arbitrage opportunity. Assuming the statistical probabilities are true, there is no chance that stock price becomes between 100 and 120. However, if a portfolio is constructed such that it has two long position of call option with strike price 110 and a long position of call option with strike 100 and 120 each(It is equivalent to sell short butterflies), it is possible to make arbitrage profit since the initial cost for constructing portfolio is negative(cash inflow of 0.25 for each portfolio) and there is no chance for cash outflow at maturity.
- (b) The statistical probabilities assumes that there is no possibility that stock price becomes between 90 and 120. However, as mentioned in (a), market price of a claim which guarantees positive payoff when stock prices becomes between 100 and 120 is positive. It implies there is a positive (risk-neutral) probability that stock price becomes between 90 and 120. In other words, statistical probabilities and market implied probabilities differ.
